Received: 10 July 2016 / Accepted: 3 February 2017

Abstract. The Oval Leaf Springs (OLS), a class of passive isolation devices, have been successfully used as anti-shock and anti-vibration mounts to protect equipment and machinery. Available literature is insufficient to understand the behavior of OLS mounts. To estimate the spring stiffness, we conducted theoretical and finite element analyses (FEA) on a large number of springs having different geometrical and mechanical properties. Based on the principle of minimum potential energy, this paper presents theoretical expressions, which describe the linear static stiffness of OLS mounts subjected to line loading in the vertical (compression) and lateral (bending–shear) in-plane directions. Comparison studies showed a good agreement between numerical and analytical models. We observed a negligible effect of transverse shearing on the spring stiffness. In addition, it was demonstrated that the stiffness is more sensitive to the radius compared to the other geometric properties of the spring. Nonlinear FEA considering the hyper-viscoelastic behavior of the damping compound showed that the OLS mounts have higher energy dissipation capabilities in the lateral direction, which increase at low frequency and large amplitude loadings.

Keywords: Oval Leaf Spring / stiffness / damping / finite element analysis / hyper-viscoelastic / energy dissipation / frequency

1 Introduction

In engineering, vibration is one of the main factors that need to be considered while designing equipment or structures. The sources of vibration can be either natural such as earthquakes and winds or man-made such as operation of heavy machinery and construction works. In many practical situations, vibrations are unavoidable, but should be within tolerable limits. During ground motions or operation of heavy machinery, vibrations may reach unacceptable levels and result in structural damage and equipment failure. Hence, adding an isolation system to suppress these vibrations becomes necessary. There are two types of isolation systems that are currently employed, namely, active and passive systems. An active system can suppress the vibration better than a passive system, however, it requires external power supply and feedback circuit to control the vibration attenuation process. Passive devices are mechanical assemblies made of different materials and designed to improve damping, stiffness, and strength of structures [1]. Contrary to actively controlled systems; passive energy dissipation devices can easily be replaced without compromising the structural integrity since they are not part of the main structure [2]. In addition, active isolation systems are design-intensive and expensive. On the other hand, a passive isolation system does not need external supply, requires easier design, and inexpensive. As a result, passive systems are the most preferred in industrial and automobile applications, such as the Oval Leaf Spring (OLS) mount shown in Figure 1.

The OLS is formed using two or more high-tensile stainless steel U-shaped leaves, joined together in the center portion with face-plates with a circular shape. The steel leaves provide the needed flexibility while the compound material enhances the damping capacity. Earlier, the Elliptical Leaf Spring, ELS (a variant of leaf spring mounts with an elliptically shaped face-plates) mountings were specifically designed for shipboard applications and were particularly suitable to protect marine equipment from shock due to underwater explosions. Later, the use of ELS mounts has been extended to isolate heavy
The Oval Leaf Spring (OLS).

machinery, air compressors, engine suspensions, and sensitive equipment. Features of the ELS mounts include the effective operation at low natural frequency and ability to attenuate large shock inputs [3].

In general, the OLS mount is a mechanical device that absorbs the vibrational energy by undergoing deformation and then release it. Hence, the strain energy of the material and the shape become a major factor in designing the springs [4,5]. The “U” shape of the ELS leaves possess the ability to act as spring and have been used in other vibration isolation devices. The behavior of “U” shaped leaves has been the subject of few studies [6 et al. [6] conducted an experimental evaluation of cyclic deformation capacity of U-shaped steel dampers for base-isolated structures. Kwon et al. [7] performed an analytical study on the shape development of U-shaped steel damper for seismic isolation system. Oh et al. [10,11] performed experimental and analytical studies on U-shaped hysteretic dampers. They reported that “U” shaped dampers could be used as energy-dissipating devices for base isolating systems since they can sustain large displacements without strength and stiffness degradation.

Tse and Lung [9] carried out finite element analysis and theoretical study on the large deflections of composite circular springs and validated their results by experiments under uniaxial tension. The authors found that the spring stiffness increased with deflection and hard spring behavior was showed throughout the whole range of applied loads. The shear and longitudinal deformations effects were found to be negligible for configurations in which the elastic modulus to shear modulus ratios were not large and the radius to thickness ratios were large. In another study, Tse et al. [8] considered the case of composite circular springs with extended flat contact surfaces and carried out finite element analysis and theoretical study on the new spring stiffness under unidirectional line loading and surface loading configurations. The authors showed that the spring stiffness increases with the increase in width and thickness of the composite spring but decreases with the increase in inner radius. However, the spring stiffnesses were more sensitive to the change in spring radius than the thickness. As an extension to the studies conducted previously by Tse et al. [8,9], Wong et al. [12] demonstrated that the reduction in spring stiffness at elevated temperatures could be prevented by the embedment of nickel-titanium alloy wire as a compound.

Several studies dealt with damping compounds and proposed the use of viscoelastic materials. For instance, Treviso et al. [13] presented a review of properties and models of damping in composite materials. Their study reported that for the damping purposes, employing a soft, viscoelastic material is preferred for the core while metals can be used for the skins. Ganapathi et al. [14] carried out a numerical study of sandwich and laminated composite beams using linear and nonlinear dynamic analysis, they used a viscoelastic material as a core to enhance their damping capacity. The results of the analyses demonstrated that increasing the core thickness enhances the damping significantly. Hao and Rao [15] reported that viscoelastic layered systems can provide a simple and flexible solution for damping vibration of sheet metal panels. They developed an analytical formulation to predict the stiffness and damping of three-layered beams with two different viscoelastic materials adjacent to each other.

Verbaan et al. [16] demonstrated the advantage of applying viscoelastic materials instead of purely viscous materials as damping medium in mechanical dampers. However, they found that at high frequencies, the stiffness increases and the damping capacity decreases significantly. This is in line with the findings of De Lima et al. [17] who conducted a time-domain modeling procedure of structures containing both viscoelastic materials and shape memory alloys (SMA) wires for vibration mitigation. The study concluded that as the excitation frequency increases, the hysteresis loop area decreases significantly, which can affect significantly the damping capability of the SMA wires. For wider frequency applications, Xu et al. [18] designed a vibration isolation device based on viscoelastic materials, which was deemed suitable for vibration suppression under wide frequency excitation. A review on the vibration damping materials like rubbers, polymers, metals, metal-matrix composites and smart materials in terms of damping capacity, stiffness, mechanical strength and figure of merit can be found in Choudhary and Kaur [19].

The main objectives of this investigation are to develop analytical solutions to the linear static stiffness and to assess the energy dissipation capabilities of OLS mounts in the vertical (compression/tension) and horizontal (bending-shear) in-plane directions. First, a series of three-dimensional linear FEA is performed to validate the analytical solutions and to investigate the effect of different properties on the in-plane spring static stiffness. Then, a nonlinear, large deflection, FEA study is conducted to characterize the effective stiffness and to assess the energy dissipation capabilities of four mounts, assuming the nonlinearity of the steel face-plates and the hyperviscoelasticity of the damping compound [13].

2 Theoretical analysis

The strain energy expression for a curved beam is a special reduced form of that for a thin shell [20]. The relative importance of strain energy $U_M$ in bending and $U_S$ in shear
loading of beams is influenced by the ratio of the length $L$, the radius $R$ of the spring to its thickness $t$ (Fig. 2), by the shape of the cross section and by the type of loading. The relative magnitude of $U_M$ and $U_S$ are examined in [21] for a given set of ratios of $L/t$, $R/t$, and given cross section. However, more accurate solutions and experimental data indicate that the strain energy due to bending $U_M$ is fairly accurate, except for relatively short beams. If the ratio of the radius of curvature to the thickness of spring is less than 5, the flexure formula is generally inadequate for describing the flexural stresses in the spring.

In this study, we assume that the dimension $R$ and $L$ are large compared to the spring thickness, $t$. Many curved members, such as closed rings and chain links, are statically indeterminate. The additional relations needed to solve for the loads are obtained using Castigliano’s theorem with appropriate boundary conditions [21]. In calculating the displacement using Castigliano’s theorem and strain energy, we are supposing that the stress is linearly distributed along the section of the spring [22]. This assumption is often made and found to be reasonable in non-circular rings where bending is the predominant mechanism of deformation. In order to establish the analytical solution, the energetic approach is used to determine the stiffnesses of the OLS mount.

2.1 Geometry description of OLS mount

Figure 2 illustrates the OLS mount considered in this study. The spring consists of two flat surfaces on top and bottom with length $2L$ and two circular portions with mean radius $R$, outer radius $R_o$ and inner radius $R_i$ from center $C$. The spring has a width $B$ and an overall thickness $t$, $t = t_e + 2t_f$, $t_f = 1.27$ mm (0.05 in.), with $t_f$ being the thickness of the face-plate. The 2D spring shows symmetry in the $x-y$ plane with the origin of $x-y$ coordinate system located at the center of the spring $O$. The advantage of this type of spring geometry is the constant value of the spring’s radius of curvature in the unstrained state, whereas in the non-circular springs (such as the elliptical leaf spring) the curvature of the spring varies at each point along the spring length, and the complexity of their analysis comes from the fact that the end torque is a function of these variable coefficients [23].

2.2 Boundary conditions and loading

The OLS is subjected to a line-loading at the centerline $A-A$ of the flat contact surface at the top while the centerline $B-B$ at the flat contact surface at the bottom is fixed. There are three cases of external force loading that are of interest: (1) vertical in-plane loading in $y$-direction, (2) horizontal in-plane loading in $x$-direction, and (3) out-of-plane loading in $z$-direction. However, in this study, we focus on the in-plane loading since the OLS is designed to operate in its plane.

2.3 Analytical solution of the static stiffness

In the development of the analytical solution to the OLS stiffness, we describe the compound's elastic modulus, $E_c$, as a fraction, $n_E$, of the facing’s elastic modulus, $E_f$ (i.e., $n_E = E_c/E_f$). In this section, we derive the in-plane vertical compressive stiffness $k_y$ and the in-plane bending-shear stiffness $k_{xy}$ of the spring.

2.3.1 Effective engineering properties

In this section we determine, through the classical laminate theory, the effective flexural stiffness, $EI_{eff}$, and the effective axial stiffness, $EA_{eff}$, which are needed to determine the stiffness of OLS mounts in the vertical and horizontal in-plane directions.

For an isotropic linear elastic material, the plane stress relationship between the Cartesian stresses and strains is:

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} Q \end{bmatrix} \begin{bmatrix} \epsilon_x \\ \epsilon_y \\ \gamma_{xy} \end{bmatrix}$$

where $[Q]$ is the stiffness matrix. Each lamina (face-plates and compound core) has a different $[Q]$. For instance, the stiffness matrix for the face-plate is given by:

$$[Q_f] = \frac{E_f}{1-v_f^2} \begin{bmatrix} 1 & v_f \\ v_f & 1 \end{bmatrix}$$

and for the compound is:

$$[Q_c] = \frac{E_c}{1-v_c^2} \begin{bmatrix} 1 & v_c \\ v_c & 1 \end{bmatrix}$$

where $v_f$ and $v_c$ are the material’s Poisson’s ratio of the face-plates and the compound, respectively. As we will see later, the Poisson’s ratio has a negligible effect on the global behavior of the OLS mounts, hence, we consider $v_f = v_c = v$. 

---

**Fig. 2.** OLS geometric properties.
The laminate extensional, $A_{ij}$, and bending, $D_{ij}$, stiffness matrices are given by:

$$[A_{ij}] = c \sum_{k=1}^{3} [Q_{ij}] t_k \left[ 1 + \frac{4}{l^2} \left( z_k^2 + \frac{t_k^2}{12} \right) \right]$$

(4)

and

$$[D_{ij}] = \sum_{k=1}^{3} [Q_{ij}] \left( t_k z_k^2 + \frac{t_k^2}{12} \right)$$

(5)

where $c$ is the shear correction factor, which is equal to 6/5 for a rectangular section. $t_k$ and $z_k$ are the thickness and location of the centroid (from the mid-plane) of the $k$th lamina, respectively.

Using the above matrices we can define the effective engineering properties of the laminate, namely, the effective exural stiffness, $EI_{eff}$, and the effective axial stiffness, $EA_{eff}$. These are given by [8]:

$$EI_{eff} = B \frac{|D|}{D_{11} D_{33} - D_{31}^2}$$

(6)

and

$$EA_{eff} = B \frac{|A|}{A_{11} A_{33} - A_{31}^2}$$

(7)

where $|D|$ and $|A|$ are the determinants of the bending and extensional stiffness matrices of the laminate. Substituting equation (4) into equation (6) and equation (5) into equation (7) yields:

$$EI_{eff} = \frac{BE_f (6t_c^2 + 12t_c^4 + 8t_c^6 + nE_t^2)}{12}$$

(8)

$$EA_{eff} = \frac{2BE_f (12t_c^2 + 6t_c^4 + 2E_t^4 + 6nE_t t_c)}{2BE_f (6t_c^2 + 12t_c^4 + 3nE_t^2 + nE_t^4)}$$

(9)

2.3.2 In-plane vertical compressive stiffness, $k_y$

The OLS is subjected to the unidirectional compression line load $F$ in the $y$-direction as shown in Figure 3(a). Due to symmetry, only one quadrant of the spring (Fig. 3(b)) needs to be considered, with a force reduced to $(F/2)$ acting on the section A–A. The bending moment $M_0$ acting on this section is statically indeterminate, hence, we shall use Castigliano’s theorem to find it, knowing that from the condition of symmetry the cross section A–A does not rotate during the bending moment of the spring.

The strain energy expression for the complete OLS mount derived from the quadrant model is:

$$U = 4(U_{AE} + U_{EC})$$

$$= 4 \left[ \int_0^L \frac{M^2}{2EI_{eff}} \, ds + \int_0^{\pi/2} \frac{M^2}{2EI_{eff}} \, R \, d\theta \right]$$

(10)

where $U_{AE}$ and $U_{EC}$ are the strain energy in the two portions AE and EC, respectively. $M$ and $E_{Ieff}$ are the bending moment and the effective flexural stiffness at any cross section of the spring, $s$ is the distance from section A to section E in the $x$-direction and $\theta$ is the angular coordinate from section E to section C. The effective flexural stiffness at any cross section is given by equation (8). By substituting the moment resultants into equation (10) we get:

$$U = \frac{4}{2EI_{eff}} \int_0^L \left( \frac{x}{2L} - M_0 \right)^2 ds$$

$$+ \int_0^{\pi/2} \left( \frac{L}{L + R \sin(\theta)} - M_0 \right)^2 R \, d\theta$$

(11)

Realizing that the displacement corresponding to $M_0$ is zero (i.e., $dU/dM_0 = 0$), we can calculate $M_0$ as:

$$M_0 = \frac{FL^2 + 2R^2 + \pi RL}{2L + \pi R}$$

(12)

Substituting into equation (11) and using Castigliano’s second theorem, the displacement in $y$-direction is obtained as:

$$\delta_y = \frac{\partial U}{\partial F}$$

$$= \frac{F(2L^4 + 4\pi RL^3 + 24R^2L^2 + 6\pi LR^3 + R^4(3\pi^2 - 24))}{12(2L + \pi R)EI_{eff}}$$

(13)

and the in-plane compression spring stiffness is:

$$k_y = \frac{12(2L + \pi R)EI_{eff}}{(2L^4 + 4\pi RL^3 + 24R^2L^2 + 6\pi LR^3 + R^4(3\pi^2 - 24))}$$

(14)
2.3.3 In-plane bending–shear stiffness, \( k_{xy} \)

The OLS is subjected to the unidirectional line load \( F \) in the \( x \)-direction at point \( A \) as shown in Figure 4(a). Due to symmetry only one half of the spring (Fig. 4(b)) needs to be considered, with the force reduced to \( F/2 \) acting on section \( A-A \). The bending moment at this section would vanish according to the principle of least work. The indeterminate shear force \( Q \) shall be determined using Castigliano’s theorem.

The strain energy due to the bending moment, \( U_M \), and the tensile influence of the force \( F \), \( U_N \), is expressed as:

\[
U = 2(U_M + U_N) = \frac{1}{E_{\text{eff}}} \int_0^L M_A^2 ds + \int_0^L M_E^2 Rd\theta + \int_0^L M_D^2 ds
+ \frac{2}{E_{\text{eff}}} \int_0^L N^2 ds
\]

where \( M_A, M_E, M_D \) are the bending moments at any section from section \( A \) to section \( E \), from section \( E \) to section \( D \), and from section \( D \) to section \( B \), respectively. \( N = -F/2 \) is the in-plane normal force. The axial stiffness, \( E_{\text{eff}} \), at any cross section is given by equation (9).

Knowing that the tangential displacement at section \( A-A \) is zero (i.e., \( dU/dQ = 0 \)), we can calculate \( Q \) as:

\[
Q = \frac{3FR(2R^2 + L^2 + \pi RL)}{4L^3 + 3\pi R^3 + 6\pi RL^2 + 24LR^2}
\]  

(16)

Substituting into equation (15) and using Castigliano’s second theorem, the displacement in \( x \)-direction is obtained as:

\[
\delta_{xy} = \frac{dU}{dF} = \frac{2E_{\text{eff}}}{FL}
+ \frac{FR^2 L^2 (10L^2 + 18RL\pi + 3R^2\pi^2)}{2E_{\text{eff}}(4L^3 + 24R^2L + 6RL^2\pi + 3R^3\pi)}
+ \frac{3FR^4(48L^2 + 16RL\pi + 3R^2\pi^2 - 16R^2)}{4E_{\text{eff}}(4L^3 + 24R^2L + 6RL^2\pi + 3R^3\pi)}
\]

(17)

and the in-plane bending–shear spring stiffness is:

\[
k_{xy} = \frac{F}{\delta_{xy}}
\]

(18)

3 Linear static behavior

To consider the transverse shearing effects that were not included in the theoretical analysis, the ANSYS finite element package (version 16.0) was used to evaluate the stiffnesses of the OLS mount. The three-dimensional SOLID95 element was selected to model the Oval Leaf Spring. The SOLID95 element defined by 20 nodes having 3 degrees of freedom per node can tolerate irregular shapes and is capable to model curved boundaries. Full model was considered in this study. The automatic meshing capability of the package meshed all models. Linear analysis was employed for this study. Table 1 summarizes the geometric properties of the OLS mounts considered in this study, where every spring is constructed using any of the possible combinations of these properties. The antivibration mounts are made of stainless steel facings (\( E_f = 200 \) GPa, \( \nu_f = 0.3 \)). The outer and inner U shaped facings, having constant thickness \( t_f = 1.27 \) mm (0.05 in.), are riveted together at the open ends with face-plates to form an oval shaped assembly. The space between the stainless steel facings is filled with a damping compound (\( E_c = n_E E_f \)). The elastic modulus of the compound material is varied to cover a wide range of possible fillings: from \( E_c = 0.05E_f \) until \( E_c = E_e \). Poisson’s ratio of the compound material is found to have negligible effect on the deflections of the spring, thus, it is kept constant at \( \nu_c = \nu_f \).

To verify the accuracy of the theoretical results obtained in the previous section, finite element analyses were performed on all springs. Then the variations of the two stiffnesses, \( k_k \) and \( k_{xy} \), with the spring’s thickness, radius, width, length, and compound material properties were determined. All nodes along the line B–B at the bottom were fixed. For the vertical in-plane load case (i.e.,

compression), nodes along the line $A$–$A$ at the top were subjected to a vertical compression line-loading and were constrained in the other directions. For the horizontal in-plane load case (i.e., bending–shear), nodes along the line $A$–$A$ were subjected to a line loading in the $x$-direction and were constrained to move in the other directions.

### 3.1 OLS without compound ($E_c = E_f$)

Table 2 summarizes the numerical and theoretical stiffnesses obtained for different values of total thickness $t$. Note that at this point there is no compound (i.e., $E_c = E_f$). It can be observed that there is a good agreement between the stiffnesses calculated using the developed equations (Eqs. (14) and (18)) and those obtained using finite element analysis. Small discrepancies between the theoretical and finite element analysis results are noted only at relatively high stiffness. Hence, the transverse shearing effect is insignificant in these cases as far as the current investigation is concerned. From Table 2, we observe that the OLS mounts are flexible in the horizontal in-plane direction and stiffer in the vertical direction.

Inner radii of 1.5 times smaller or bigger than 50 mm (i.e., 38 mm and 85 mm) were also used in the current investigation in order to study the size effect on spring stiffnesses. Within the boundaries of variation in $R$ and $t$ in the current investigation, it can be observed from Figure 5 that an increase in the spring thickness would not be an effective way to increase the stiffness of OLS with large inner radius (i.e., in the range between 85 and 100 mm). The effectiveness of increasing stiffness by means of increasing the thickness was more pronounced for the OLS mounts with relatively small inner radii (i.e., in the range between 38 and 50 mm). Furthermore, the stiffness increases as the radius decreases and it is more sensitive to the change in OLS radius than its thickness. From the theoretical expressions of $k_y$ and $k_{xy}$, it is clear that the stiffness is inversely proportional to the cubic of radius $R$.

Variation of the stiffness with thickness and width are depicted in Figure 6. It can be seen that all the spring stiffnesses are highly dependent on the thickness and...
width. In other words, one of the most effective ways to adjust the OLS stiffness at low radius and length (when \(R/t\) and \(L/t\) are close to 5) is to alter the thickness or the width. Furthermore, the theoretical solution (Eqs. (14) and (18)) predicts that \(k_y\) and \(k_{xy}\) are linearly proportional to the width \(B\) of the OLS and cubically proportional to the thickness \(t\).

As shown in Figure 6(b), all curves have a similar trend (for \(k_y\) and \(k_{xy}\)); the stiffness in all directions increases significantly with the increase in thickness. Figure 6(a) shows the influence of width on the OLS stiffnesses. With a constant length, radius, and thickness, the spring stiffnesses \(k_y\) and \(k_{xy}\) increase linearly with the spring width.

### 3.2 OLS with compound \((E_c \neq E_f)\)

Tables 3 and 4 compare the theoretical and numerical results obtained for a selected number of springs. Again, we observe a good agreement between the two solutions. Results of the finite element analyses performed on the springs with different material and geometric properties are plotted in Figures 7–10.

#### 3.2.1 Effect of compound’s elastic modulus \((E_c)\)

Figure 7 shows the variation of the average normalized spring stiffnesses \(k_y/k_y(E_c = E_f)\) and \(k_{xy}/k_{xy}(E_c = E_f)\) with \(n_E\). It is clear that the normalized stiffnesses increase linearly with the compound material elastic modulus, \(E_c\), and this variation can easily be demonstrated to be independent of the spring width, \(B\), face-plate length, \(L\), and radius, \(R\). Both \(k_y\) and \(k_{xy}\) are more sensitive to \(E_c\) for thick springs. Analytically, the normalized stiffnesses can be calculated to be:

\[
\frac{k_y}{k_y(n_E=1)} = 1 - n_t^3(1 - n_E) \approx \frac{k_{xy}}{k_{xy}(n_E=1)}
\]

where \(n_t = t_c/t\) is the core to total spring thickness ratio. Equation (19) can be used to calculate the stiffness based on the stiffness of the same spring with one material \((E_c = E_f = E)\).

#### 3.2.2 Effect of compound’s thickness \((t_c)\)

Figure 8 shows the variation of the normalized stiffness \(k_y/k_y(n_t = 0)\) and \(k_{xy}/k_{xy}(n_t = 0)\) with the variation of the core to total thickness ratio, \(n_t = t_c/t\). It is clear that \(n_t\) has a considerable effect on the variation of the normalized stiffness; an increase in \(n_t\) increases significantly the normalized stiffness of the spring in all directions, especially for high values of \(n_E\). Analytically, the normalized stiffness can be calculated to be:

\[
\frac{k_y}{k_y(n_t=0)} = \frac{1 - n_t^3(1 - n_E)}{(1 - n_t)^3} \approx \frac{k_{xy}}{k_{xy}(n_t=1)}
\]

#### 3.2.3 Effect of the spring radius \((R)\)

Figure 9 plots the variation of the normalized stiffness \(k_y/k_y(R = 38\, \text{mm})\) and \(k_{xy}/k_{xy}(R = 38\, \text{mm})\) with the spring radius, \(R\), for different face-plate lengths. It is observed that an increase in the radius decreases considerably the spring compressive stiffness, especially for short face-plate lengths, \(L\). An increase in the radius induces a cubic decrease of the spring stiffnesses \(k_y\) and \(k_{xy}\). This confirms the analytical solutions presented in equations (14) and (18). In addition, the effect of increased \(R\) in reducing the compressive stiffness, \(k_y\), is more pronounced for short faceplate lengths. However, the effect of \(L\) on the normalized bending/shear stiffness, \(k_{xy}\) is insignificant compared to \(R\).

#### 3.2.4 Effect of the spring length \((L)\)

To study the effect of spring length on the stiffnesses, the length \(L\) of the face-plate (total face-plate length is \(2L\)) was varied to cover a wide range of practical OLS mounts and
the stiffness was recorded for each spring length, the results are reported in Figure 10. It is clear that the OLS stiffness is highly dependent on the length of the flat surface. An increase in L reduces considerably the spring stiffnesses, this influence is more pronounced for smaller values of R.

3.2.5 Effect of the spring width (B)

From equations (14) and (18) it is clear that the compressive stiffness and bending–shear stiffness increase linearly with the increase in spring width, B.

3.3 Relationship between the compressive stiffness and bending–shear stiffness

To investigate the relationship between the spring compressive stiffness, $k_p$, and bending–shear stiffness, $k_{xy}$, the ratio $\varphi = k_p/k_{xy}$ is calculated for all OLS mounts constructed based on all possible combinations of the geometric properties shown in Table 1. Table 5 summarizes the average ratio, $\varphi_{avg}$, with the corresponding values of L and R. The standard deviation, $\sigma_{\varphi}$, is provided.
Table 3. Comparison of numerical and theoretical stiffness of OLS mounts with $E_c = 0.05 E_f$.

to measure how widely the $\varphi$ values are dispersed from $\varphi_{avg}$. Interestingly, the $\varphi$ ratio is almost independent of all spring properties except $L$ and $R$.

From the analytical stiffness expressions (Eqs. (14) and (18)) we can calculate the sensitivities of $\varphi$ to the variation of $B$, $t$, $t_p$, and $n_E$, by computing the derivative of $\varphi$ with respect to each of these parameters. The obtained derivatives are almost equal to zero, indicating that the $\varphi$ ratio is insensitive to the variation of these parameters.

### 3.4 The special case of very soft compounds

In the special case of very soft compounds such as elastomers, which are characterized by a negligible elastic modulus compared to the face-plates material (i.e., stainless steel), the theoretical formulas for the stiffness in the vertical (Eq. (14)) and in the lateral (Eq. (18)) directions need to be modified to provide accurate estimations. For this reason, several OLS mounts with different geometric and compound material properties were analyzed using ANSYS and the obtained static stiffness, in each direction, was compared to the stiffness calculated using the proposed analytical formulas with $n_E=1$. Next, a multivariate nonlinear regression analysis was used to fit the ratios $\frac{k_{y,\text{FEA}}}{k_{y,\text{Theory}}}$ to the following equation:

$$\frac{k_{y,\text{FEA}}}{k_{y,\text{Theory}}} = a e^{BLR+cL+dR+e}$$

in which $a$, $b$, $c$, $d$, $e$ are fitting constants to be determined for each loading direction. For the stiffness ratio in the vertical direction $a = 2.451$, $b = 5.08 \times 10^{-6}$, $c = 2.06 \times 10^{-3}$, $d = 3.28 \times 10^{-3}$, $e = 2.8377$, and in the lateral direction $a = 2.987$, $b = -16.5 \times 10^{-6}$, $c = 4.45 \times 10^{-3}$, $d = 7.17 \times 10^{-3}$, $e = -2.8365$. Therefore, the vertical stiffness, $k_{y,\text{FEA}}$, of an OLS mount with a very soft damping compound is determined based on the vertical stiffness calculated using equation (14) with $n_E=1$, $k_{y,\text{Eq. (14)}}$, that is:

$$k_{y,\text{FEA}} \approx \frac{k_{y,\text{Eq. (14)}}}{k_{y,\text{Eq. (14)}}} \times 2.451 e^{0.08 \times 10^{-6} LR + 2.06 \times 10^{-3} L + 3.28 \times 10^{-3} R + 2.8377}$$

(22)

Similarly, the stiffness in the lateral direction, $k_{xy,\text{FEA}}$, is calculated based on equation (18) with as follows:

$$k_{xy,\text{FEA}} \approx \frac{k_{xy,\text{Eq. (18)}}}{k_{xy,\text{Eq. (18)}}} \times 2.987 e^{-16.5 \times 10^{-6} LR + 4.45 \times 10^{-3} L + 7.17 \times 10^{-3} R - 2.8385}$$

(23)

Figure 11 compares the vertical and lateral stiffness ratios $\frac{k_{y,\text{FEA}}}{k_{y,\text{Theory}}}$ to the ratios obtained using equations (22) and (23), respectively. Clearly, a good agreement is seen between both results. Note, that the OLS mount width, $B$, was found to have an insignificant influence on both stiffness ratios.

### 4 Nonlinear cyclic behavior

In this section, the cyclic behavior of OLS mounts is investigated assuming material and geometric nonlinearities. For this purpose, a series of three-dimensional nonlinear finite element analysis (NLFEA) were carried out on four mounts (Tab. 6) using ANSYS. The hysteretic behavior and energy dissipation of each mount are assessed assuming the two loading cases: compression/tension (vertical direction) and bending–shear (lateral direction).
4.1 Finite element modeling

Both material and geometric nonlinearities with large deformation have been considered. All parts of the mounts were modeled using SOLID186 elements (Fig. 12). SOLID186 element is a higher-order 3D node element that exhibits quadratic displacement behavior and supports plastic, hyperelastic, and large deformation capabilities. The automatic meshing capability offered by ANSYS was employed. The boundary conditions and load application regions are as shown in Figure 12.

To assess their cyclic behavior in the compression/tension direction, the OLS mounts were subjected to vertical cyclic displacements with increasing amplitude: 5, 10, and 20 mm. To consider the effect of the rate of loading, four loading frequencies were assumed for each displacement amplitude: 0.25, 0.5, 1, and 3 Hz (Fig. 13). In the bending–shear direction, the cyclic behavior of the mounts was assessed by applying horizontal displacements consisting of the same displacement time histories applied in the vertical direction (Fig. 13). Note that the input displacement amplitudes correspond, roughly, to shear strains of 2.7, 5.4, and 11.4%.

4.2 Material data

4.2.1 Compound’s material

The compound’s material consists of rubber, which is known for its damping properties and has been used in many shock and vibration isolation mounts [24,25]. High damping rubbers exhibit both hyperelasticity and viscoelasticity, hence are modeled using hyper-viscoelastic constitutive material models.

Different constitutive models are available to represent the hyperelasticity of rubber-like materials [26]. In this study, Ogden model [27] is used to simulate the rubber behavior, which is defined using the strain energy potential function in the form:

\[ W = \sum_{i=1}^{N} \frac{\mu_i}{a_i} (\lambda_1^{a_i} + \lambda_2^{a_i} + \lambda_3^{a_i} + 3) + \sum_{i=1}^{N} \frac{1}{d_i} (J - 1)^{2i} \]  \hspace{1cm} (24)

in which, the initial shear modulus, \( \mu_i \), is given by:

\[ \mu = \sum_{i=1}^{N} a_i \mu_i \]  \hspace{1cm} (25)

and the initial bulk modulus is:

\[ k = \frac{2}{d_i} \]  \hspace{1cm} (26)

In equation (24), \( \mu_i \) and \( a_i \) are the primary fitting parameters, \( \lambda_i (i=1, 2, 3) \) represents three principal stretches, and \( N \) is the material constant (\( N \leq 3 \)) and represent the fitting parameters to the volumetric deformation and material Jacobian, respectively. The formulas for stress given strain can be derived from the

![Fig. 11. Comparison of OLSs stiffness ratios.](image-url)
strain energy potential function (Eq. (24)). By using experimental test data, a least-squares fit of the stress–strain equations can be computed to determine the parameters of the hyperelastic model [28–31].

The viscoelasticity, on the other hand, combines both, elasticity and viscosity. The elastic behavior characterizes the tendency of the material to store energy while the viscosity characterizes its tendency to dissipate that energy.
energy. The combination of such behaviors leads to a rate-dependent behavior. Therefore, modeling of viscoelastic materials requires nonlinear constitutive laws to describe their complex behavior. In most FEA software, the viscoelasticity is modeled using Prony series, in which the shear modulus is expressed as follows:

\[ G(t) = G_0 + \sum_{i=1}^{n} \alpha^G_i \exp\left(-\frac{t}{\tau^G_i}\right) \]  

where \( G_0 \) is the relaxation shear modulus at time \( t = 0 \); \( n \) is the number of Prony terms; \( \alpha^G_i \) is the relative modulus, \( \alpha^G_i = 1 - \sum_{i=1}^{n} \alpha^G_i \); and \( \tau^G_i \) is the relaxation time.

In the current investigation, the damping compound’s material data are selected as shown in Figure 14. The parameters of the compound’s material (at room temperature) were taken from Zhang et al. [32] and consist of the following:

- Ogden three-data points model of the hyperelastic behavior (Fig. 14(a)): \( \mu_1 = 18.9 \times 10^3 \) Pa, \( \mu_2 = 3.6 \times 10^3 \) Pa, \( \mu_3 = -3 \times 10^3 \) Pa, \( a_1 = 1.3, \ a_2 = 5, \ a_3 = -2 \);
- Prony series model of the viscoelastic behavior (Fig. 14(b)): \( \alpha_1 = \alpha_2 = 1/3, \ \tau_1 = 0.4 \) s, \( \tau_2 = 0.2 \) s.

4.2.2 Face plates material

The steel material of the face plates is represented by a bilinear model with kinematic strain hardening (Fig. 15) with Young’s modulus \( E_f = 193 \) GPa, yield stress \( \sigma_y = 240 \) MPa, strain hardening modulus \( E_t = 0.01 \ E_f \), and Poisson’s ratio \( v_f = 0.3 \).

4.3 Results and discussion

First, a small static displacement was applied to the four OLS mounts to determine their static stiffness in both, vertical and lateral directions. The obtained stiffness values are reported in Table 7 along with those computed using equations (22) and (23). A good agreement between the two approaches is achieved. As the compound thickness increases, the theoretical solution becomes more accurate. Mounts with very thin compounds, such as OLS1 are not very practical for their low damping properties. Therefore, the proposed equations are more accurate for the range of practical geometries.

In what follows the cyclic behavior of vibration mounts is discussed with respect to the two loading cases under different cyclic motion frequencies.

![Fig. 14. Material data for rubber: (a) hyperelasticity and (b) viscoelasticity.](image)

![Fig. 15. Material data for steel.](image)
4.3.1 Vertical cyclic behavior

For the vertical (compression/tension) direction, the force-displacement curves of the four OLS mounts are shown in Figure 16. For clarity, only two cyclic motion frequencies are reported: 0.25 Hz and 3 Hz. All mounts exhibited asymmetric hysteresis behavior. The mounts showed softening behavior while in compression and hardening behavior in tension. The difference between the tensile and compressive stiffnesses is related to the tensile/compressive stiffness of the rubber, as well as the compressive stiffness being influenced by additional factors such as geometry characteristics. Similar observations were reported by [33]. In addition, in the vertical direction, the mounts are softer when subjected to low frequency motions and stiffer under higher frequencies.

![Fig. 16. Vertical force-displacement curves for two loading frequencies.](image)

(a) OLS1  
(b) OLS2  
(c) OLS3  
(d) OLS4
Under high loading frequency (i.e., 3 Hz), the hysteresis loops are narrower, indicating low energy dissipation and almost linear behavior, especially for mounts with thin rubber compound (e.g., OLS1). As the loading frequency decreases, the hysteresis loops become wider, suggesting higher energy dissipation capability, particularly for the mounts with thicker compound.

To check the contribution of the steel material nonlinearity on the overall behavior of the OLS mounts, a linear steel material (with $E_f = 193$ GPa and $\nu_f = 0.3$) was assumed for the face-plates while keeping the compound’s material as is (i.e., hyper-viscoelastic) in a new series of FEA. Figure 17(a) clearly demonstrates that the hysteresis behavior of OLS4, for example, is not affected by the nonlinearity of the steel, suggesting that both, the stiffness and energy dissipation per cycle are not dependent on the face-plates material nonlinearity, at least up to the highest considered level of loading amplitude (i.e., 20 mm).

4.3.3 Effective stiffness and energy dissipation

To further characterize the cyclic response of the OLS mounts, the effective stiffness and energy dissipation per cycle were determined for each loading frequency and amplitude. The effective stiffness for each cycle is calculated for units with viscoelastic behavior as per Eurocode 8 [34]:

$$k_{eff} = \frac{F^+ - F^-}{d^+ - d^-}$$

in which $d^+$ and $d^-$ are the maximum positive, respectively, the maximum negative displacement achieved by the OLS, while $F^+$ and $F^-$ are the corresponding force reactions. The energy dissipated per cycle, which serves as an estimate of the level of damping, is calculated as the area under the hysteresis loop.

4.3.2 Lateral cyclic behavior

Figure 18 shows the force–displacement curves of OLS mounts in the in-plane (bending–shear) horizontal direction. The response of the OLS mounts showed linear behavior when subjected to small displacement amplitudes (i.e., 5 mm), and nonlinear behavior for larger amplitudes. Under high frequency lateral loadings (i.e., 3 Hz), the hysteresis loops are narrower, however, they become wider for thicker compound mounts. In the lateral direction, the mounts are softer when subjected to low frequency motions and stiffer under higher frequencies.

The stiff response at small displacement amplitudes is desirable to limit the horizontal movement of isolated equipment during high frequency vibrations. At large loading amplitudes, the flexibility of the isolators lengthens the period of the isolated equipment, thus reducing the acceleration response. Unlike in the vertical direction, the hysteresis loops were larger and symmetric in the lateral direction (see Fig. 18). The amount of energy dissipated per cycle is highly dependent on both, the amplitude and the rate of loadings. As in the vertical direction, Figure 17(b) shows that in the lateral direction, the hysteresis behavior is not affected by the nonlinearity of the steel face-plates, at least up to the highest considered level of loading amplitude (i.e., 20 mm).
Fig. 18. Lateral force–displacement curves for two loading frequencies.

Fig. 19. Variation of the effective stiffness (at 20 mm displacement amplitude) with the frequency of loading in the (a) vertical and (b) lateral directions.
Tables 8 and 9 report the percentage of change in the effective stiffness of the four OLS mounts from 0.25 Hz to 3 Hz loading frequencies in the vertical and lateral directions, respectively. Clearly, for mounts with thinner compounds, the effective stiffness increases by smaller amounts and as the compound becomes thicker, the
increase can reach up till 30% in the vertical direction and 70% in the lateral direction. Note that in the lateral direction, the effective stiffness increases by larger amounts compared to the vertical direction.

Moreover, the effective stiffness is almost insensitive to the change in loading amplitude, until 20 mm (see Figs. 20 and 21).

4.3.3.2 Energy dissipation

The variation of the cumulative dissipated energy with the loading frequency is shown in Figure 22. From 0.25 Hz to 0.5 Hz, the cumulative dissipated energy increases, reaching the peak at 0.5 Hz suggesting that the material is more dissipative at this frequency, then decreases at higher frequencies, especially for mounts with thick damping.
compounds. Furthermore, when loaded in the lateral direction, the OLS mounts dissipate more energy than in vertical direction.

Unlike the trend seen in the effective stiffness, the energy dissipated per cycle increases with the loading amplitude (Figs. 23 and 24). Noticeably, the OLS mounts are more suitable to isolate equipment subjected to low frequency, high amplitude vibrations.

5 Conclusions

In this study, analytical models have been developed to estimate the elastic stiffness of the Oval Leaf Spring mounts (OLS) under unidirectional line-loading configuration. The FEA performed on several OLS mounts proved the accuracy of the proposed theoretical expressions in predicting the spring stiffnesses in the vertical and horizontal in-plane directions, even with included transverse shearing effects. The developed analytical models satisfactorily predict the behavior observed in the FEM results of the mounts, such as:

- the major stiffness is in the vertical direction;
- all spring stiffnesses increase with increase in thickness and width of the OLS but decrease with increase in radius;
- the spring stiffnesses are more sensitive to the change in OLS radius than its thickness;
- an increase in the damping compound thickness reduces the stiffness of the OLS mount in all directions;
- the spring stiffness is highly dependent on the length of the flat surface; an increase in the length decreases the spring stiffness;
- the compressive stiffness to the bending–shear stiffness ratio depends only on the face-plate length and spring radius.

Furthermore, to assess the effective stiffness and energy dissipation capacity of the mounts, a series of three-dimensional NLFEA have been carried out considering both, the hyper-viscoelastic behavior of the damping compound and the nonlinearity of the steel face-plates. The investigation has led to draw the following conclusions:

- the force–displacement hysteretic loops of the OLS mounts show good energy dissipation capability under low frequency and this capacity increases with the loading amplitudes;
- the effective stiffness increases with the frequency of loading;
- the influence of the displacement amplitude on the effective stiffness is relatively smaller compared with the frequency of loading and thickness of the compound;
- increasing the damping compound thickness enhances significantly the energy dissipation.
This paper is based upon the work supported by the University of Sharjah under the competitive grant scheme (Innovative Vibration Attenuation Devices for Equipment and Structures) and the National School of Built and Ground Works Engineering, Algeria.
